FOREWORD

The chemical, physical and biological characteristics of surface waters are interrelated phenomena. Making greater use of the stream biota to determine existing, and to forecast future, water quality in the stream offers promising possibilities. Plankton studies within the National Water Quality Network have included extensive work designed to permit application of the principle of diatom species diversity to the development of water quality indices. The studies required development of new laboratory analytical techniques, as well as preliminary application of the methodology to surface water samples from the many diverse Network sampling points.

Published herein are data from samples collected in the 2-year period July 1959 through June 1961 at 65 of the Network stations. While this work is continuing within the Network program, it is hoped that the material here presented will enable workers in this field to evaluate the techniques described by applying them more broadly.

Charts of Sampling Stations

The National Water Quality Network

The Public Health Service program for providing fundamental information on the quality of the Nation's waters stems from Public Law 660, approved July 9, 1956, as amended by Public Law 87–88, July 20, 1961. Section 4(c) thereof states: ". . . the Secretary [of Health, Education, and Welfare] shall, in cooperation with other Federal, State, and local agencies having related responsibilities, collect and disseminate basic data on chemical, physical, and biological water quality insofar as such data or other information relate to water pollution and the prevention and control therof."

To fulfill this responsibility, the National Water Quality Network collects, interprets, and disseminates:

a. Information on changes in water quality at key points in river systems, as such quality may be affected by changes in water use and development.

b. Continuous information on the nature and extent of pollutants affecting water quality.

c. Data which will be useful in the development of comprehensive water resources programs.

d. Data which will assist State, interstate, and other agencies in their water pollution control programs, and in the selection of sites for legitimate water uses.

Some 50 sampling stations were established when the program started, October 1, 1957. By January 1, 1962, the number had grown to 102.

Each sampling location satisfied one or more of the following criteria:

a. Major waterways used for public water supply, propagation of fish and wildlife, recreational purposes, and agricultural, industrial, and other legitimate uses.

b. Interstate, coastal, and international boundary waters.

c. Waters on which activities of the Federal Government may have an impact.

Sampling station sites are fixed only after consultation with local, State, Federal and other agencies having related interests.

Active local participation is important in this operation. It assures maximum development of all information valuable both locally and nationally. Program costs are shared by the Federal Government and State and local agencies, those of the latter through contributions of laboratory and sampling manpower. Specifically, the State and local agencies perform most of the conventional chemical analyses and collect samples for the newer, more complex examinations. The Public Health Service, in turn, performs the more complex determinations and makes the results available to the participants. In addition, the consultation, training facilities, and other resources of the Public Health Service are available to the cooperating agencies.

Locations of sampling stations in operation as of January 1, 1962, are shown on page 3. Descriptions of the stations, participating agencies, and other pertinent information are presented on pages 5–8.

Only after careful screening of needs in water resource development was a pattern set for analyses of water samples. All Network samplings are examined for:

a. Radioactivity.
   (1) Gross alpha.
   (2) Gross beta
   (3) Strontium 90
b. Plankton populations.
c. Coliform organisms.
d. Organic chemicals
e. Biochemical, chemical, and physical measurements, including biochemical oxygen demand (B.O.D.), dissolved oxygen (D.O.), chemical oxygen demand (C.O.D.), chlorine demand, ammonia nitrogen, hydrogen ion concentration (pH), color turbidity, temperature, alkalinity (or acidity), hardness, chloride, sulfate, phosphates, and total dissolved solids.
f. Trace elements.

Samples for groups a, c, and e are collected and analyzed weekly. Samples for organic chemicals are collected monthly, while the schedule for plankton organism examinations is semimonthly. Strontium 90 analyses are made on composites of weekly samples accumulated over a 3-month period. Trace elements are determined on 2-month composites of weekly samples. New parameters which are developed and found significant are included as the program continues.

Water Quality Parameters

In the assessment of water quality, all of the legitimate purposes for which raw waters can be used, and which may be affected by pollution, must be considered. These may range from the minimum requirements necessary for navigation to the ultimate in water quality demanded for special industrial processing. Quality needs differ considerably, therefore, according to water use.

For domestic use water must be free of disease organisms, clear, colorless, taste- and odor-free, and must have a relatively low dissolved mineral content. Agricultural water is judged primarily on its mineral content, especially with respect to the ratio between sodium and other cations, and the presence of boron. Water for fish propagation and recreational purposes must be relatively free from domestic and industrial pollution and must be able to sustain an active flora of the smaller aquatic organisms on which fish and wildlife feed. Industrial water quality demands run the gamut from the complete absense of minerals to a requirement of low temperature, the critical factor in water used for cooling. The effects of radioactive materials on these uses have not yet been fully appraised.

National Water Quality Network Sampling Stations

Introduction to the Plankton Studies

Although many water quality and water pollution studies have been made of rivers, there has been relatively little investigation of plankton in relation to water quality. This supplemental report presents information on the plankton populations found at 65 selected stations of the National Water Quality Network. Findings reported are based upon semimonthly samplings over a 2-year period ending June 30, 1961.

Plankton are composed of algae and other plant and animal organisms, and they do have an important relationship to the quality of the water in which they live. Always present in lakes and streams, these minute organisms are vital to water's self purification process. They take up and concentrate radionuclides from the water and when the cells die, they release radionuclides in the water.

Plankton also provide food for fish and other aquatic life. They sometimes cause taste and odor problems in water supplies. They may hinder water treatment by clogging filters. Often they become so abundant as to cause a nuisance in recreational areas and deplete oxygen in the water during decomposition. Because they exhibit population dynamics, plankton can serve as important indicators of water quality. For example, pollutants in the water may alter drastically the normal population patterns of plankton—an effect which may be observed through plankton population studies.

The data herein documented will be especially valuable because identification and enumeration of the organisms were given uniform treatment, making comparisons relevant. Most other studies deal only with the larger net plankton and are not year-round studies.

In 1957 when the Network program was inaugurated, 16 sampling stations were in use on a monthly basis. At this time all diatoms including empty shells were included in the total counts. By 1959 the sampling schedule became semimonthly and the inert diatom shells were counted, separated and excluded from the total phytoplankton counts. The clump count procedure is used to tally the plankton organisms per ml. This includes all of the preservable algae larger than bacteria. In this method each single cell and natural clump or colony is recognized as a unit. From these data one may use a factor to determine other standard units.

All plankton which can be recognized in the preserved samples are being identified. These include fungi, sheathed bacteria, protozoa, crustaceans, rotifers, nematodes, and other invertebrates. Although these represent a small segment of the total population, their presence is noted for possible future use in studies of their relationship to water quality.

Much of the emphasis in the plankton program has been on diatoms. Both in total population and number of species they constitute the largest planktonic group in the rivers and Great Lakes. They are important indicators of water quality and its variations.

Equipment, Materials and Methods

Samples of raw water are collected semimonthly from each Network station and sent for processing to the Public Health Service's Water Quality Laboratory, Cincinnati, Ohio. Each sample is taken directly from the river or lake, or from a continuously flowing intake (as at a water treatment plant) receiving the river or lake water.

The sample, consisting of three liters of untreated water, is added to 100 ml. of preservative (thimerosal, 0.16 percent, plus Lugol's solution, 1 percent) in a polyethylene sample bottle. The Lugol's solution stains parts of the cells making identification easier. It also aids in settling the plankton since the iodine causes some of them to lose gas and, therefore, their buoyancy. This preservative has been found to be effective for approximately 1 month during the warm seasons and longer during cool weather. One gram of sodium borate is added for each gram of thimerosal to help keep the thimerosal in solution.

Three analyses, each requiring one liter, are performed per sample: (1) the genera of phytoplankters are identified and enumerated using the Sedgwick-Rafter slide technique; (2) the genera of microinvertebrates, mostly rotifers and crustaceans, are settled, identified to genus and counted in a special microslide; and (3) the diatoms are settled, washed and made into a permanent hyrax slide from which are made proportional counts of the species and some of the varieties. These determinations are also used to qualitate to genus the diatoms recorded in the Sedgwick-Rafter (step one) procedure and to make the proportional counts in step three.

Phytoplankters counted in the Sedgwick-Rafter slide include forms, measuring four microns or more. Clump counts are made of fungi and sheathed bacteria. The Sedgwick-Rafter counts for total algae that were alive when collected are made as clump counts in which each single-celled individual or natural clump or colony of cells is enumerated as one. Diatom shells without chromatophores are tallied separately from preserved diatoms with chromatophores.

Because tiny centric and pennate diatoms cannot be adequately identified to genus from the Sedgwick-Rafter slide, their determination is dependent on accurate identification during proportional counting from permanent hyrax slides. However, all other algae are determined to genus, including the colonial diatoms *Melosira*, *Asterionella*, *Fragilaria* and *Tabellaria*. These diatoms form natural aggregates or colonies and can be recognized in a Sedgwick-Rafter cell. All other diatoms, however, are counted only as centrics or pennates since identification, even to genus, is often obscure with the resolution and magnification (200X) available in the Sedgwick-Rafter method. The identification and relative abundance of various diatom species are determined from a permanent hyrax slide and these findings are used to identify the genera of the diatoms in each Sedgwick-Rafter count.

In concentrating by centrifugation of raw samples low in phytoplankton a moderate proportion of buoyant forms is lost, broken apart or so compacted with their spines or gelatinous secretions that they cannot be redistributed randomly for counting under the microscope. For these reasons most of the quantitation of phytoplankters has been obtained from unconcentrated or undiluted raw water samples. The count is in a Sedgwick-Rafter slide using 20-power objectives and 10-power oculars, and is accomplished by

counting two lengthwise strips (about 500 microns) the width of the Whipple square.

These two strips represent a volume of about 0.05 ml. To obtain the number of plankters per ml., a factor of 20 to 22 is used, varying with the correction for preservative dilution and differences in calibration of the microscopes. Precise techniques have been developed for obtaining representative and geometrically accurate one-ml. samples for counting in the Sedgwick-Rafter slide.

For the rare occasions where concentrations of phytoplankton were necessary, settling proved to be the best method, affording the least loss or distortion of organisms. Furthermore, this concentration technique has the advantage of allowing the sediment to be washed with distilled water to free it of colloidal material and some of the silt particles, which interfere with optics in some of the turbid samples.

Identification of diatom species and their proportional census is done from incinerated frustules of diatoms settled and washed from a liter of sample. The washed sediment containing the diatoms is dried on a warming table on a number one coverglass, and this sediment is ashed in place on the coverslip on a red-hot hotplate. This method does not appear to change the minute identification markings of the siliceous cell walls and enables the two valves (epitheca and hypotheca), as well as the groups of cells attached to one another, to remain in a natural grouping, so that Sedgwick-Rafter counts and proportional counts can be matched.

Chemical cleaning was abandoned because bubbling separates the valves, distorts natural cell grouping, and tends to inflate the actual count. Permanent slide mounts are made with hyrax medium. The technique of settling, washing in distilled water, and mounting does not appear to alter the uniformity of the diatom species composition. Proportional counts are made with 90-power oil immersion apochromatic objectives and 10-power oculars containing a Whipple micrometer grid. Random strip counts are made until the total number of units reaches 200 to 300. Higher counts are necessary when one or two species are overwhelmingly abundant.

Identification to species is facilitated by the described techniques in settling, washing and hyrax preparation, and by the use of the best optical lenses available.

Proportional counting of diatoms from permanent slides is on a modified unit-area basis, in which each single cell or each portion of a natural aggregate occupying up to 300 square microns is tallied as one unit, cells or aggregates occupying from 300 to 1,000 square microns as two, those 1,000 to 2,500 square microns as three, those 2,500 to 5,000 square microns as four, and those over 5,000 square microns as five. The Whipple grid makes this scaling simple. This system gives a slight weighting to the larger specimens and colonies, which are seldom numerically abundant, but it is basically the same as the Sedgwick-Rafter count used for enumerating the other phytoplankters. About 95 percent of the cells or clumps naturally fall into size class one or two.

Proportional Counting

The numbers and kinds of diatoms obtained from the one-liter sample aliquot usually provide sufficient organisms for a kinds-to-numbers determination. This involves identifying and counting enough diatoms of the four most abundant species and the remainder. For this analysis, counting of great numbers was found unnecessary; the percentages of the total diatom count are determined for the four most numerous species after counting only about 250 or so individuals. Further counting does not significantly change the proportion of the total population thus found to be represented by the four predominant species.

This more rapid method of determining the species diversity by using diatoms was developed because of the large number of samples processed from the National Water Quality Network. A trained counter requires about 45 minutes to read an average slide.

Some generalizations about community dynamics are possible because a separate tally is maintained for each species. The diatom charts (pages 15 and 16), showing the relative occurrence of the four species most abundant at 65 stations, dramatically show the distribution and species character of the Network.

Biotic Characterization of Waterways

The organisms most abundant at any sampling station at any given time are the most reliable key to conditions of the environment. Species present in relatively lower numbers may not be reliable for this purpose because they sometimes represent organisms washed into the stream from ponds, creeks and other minor aquatic habitats. Furthermore, the flowing together of two unlike principal streams may produce a segment of mixing water containing organisms that do not represent true environmental conditions. Surviving healthy organisms become reliable indicators when they continue to multiply in the new water mixture and become predominant.

The four most abundant diatom species reflect in most situations the environmental conditions in the streams and Great Lakes. They were used during this investigation to indicate differences in water quality and other environmental conditions. Rare organisms are frequently encountered in streams that receive biota from other streams or lakes with unlike environments. Relatively dense, healthy plankton populations of several species, however, are very useful, because they usually represent favorable environmental conditions.

In analyzing the plankton from the same rivers and lakes for over three years, one is impressed with the "personality" of each river and many of its stations, based on the kinds of dominant biota each supports. The person engaged in plankton identification and enumeration soon learns to recognize many of the rivers and even individual stations by the characteristic plankton each produces. The table on page 13, wherein letters are used to show the presence of individual species, reveals the similarities among stations on a given stream. For example, similarities are noted between the stations of the Great Lakes and between those of the Columbia River. Also, the Southeast, the Northeast, the Southwest, and the upper and lower Mississippi River each have their characteristic diatom floras.

A decided marine influence at three of the Network stations is evidenced by the brackish diatoms always present. These are Poughkeepsie, New York on the Hudson River; Port Wentworth, Georgia on the Savannah River; and Philadelphia, Pennsylvania on the Delaware River. In addition, the diatoms of Port Wentworth include species typical of the South Atlantic coastal waters.

Some other coastal stations have shown marine influence after periods of low rainfall, which allows brackish water to back up during periods of high tide. *Cyclotella striata* is the most common species from these stations, but brackish species of *Coscinodiscus denarus* are also numerous.

Diatoms found in large numbers in all major drainage basins and the Great Lakes are *Diatoma vulgare*, *Fragilaria crotonensis*, *Melosira ambigua*, *Melosira granulata*, and *Stephanodiscus hantzschii*.

Diatoms characteristic of the Great Lakes (absent or extremely rare at river stations) are *Cyclotella comta*, *Cyclotella kutzingiana*, *Melosira binderana*, *Melosira islandica* and *Rhizosolenia eriense*.

Diatoms characteristic of the Arkansas, Colorado and Rio Grande rivers (arid regions with waters of high calcium carbonate hardness and often with high dissolved salts) are *Amphiprora alata*, *Amphiprora paludosa*, *Amphora ovalis*, *Biddulphia laevis*, *Caloneis amphisbaena*,

642423 O—62——8

Pleurosigma delicatula, *Surirella brightwellii* and *Surirella striatula*. In the Red River (south) *Diploneis smithii* dominate.

Certain diatoms dominate for short periods at widely separated stations, but are characteristic for these stations by their abundance and high fidelity. The Southeast is represented by *Cyclotella pseudostelligera* and *Melosira distans* variety *alpigena*. Buffalo, New York and Peoria, Illinois are identified by the high incidence of *Stephanodiscus niagarae*. While *Tabellaria fenestrata* is widely distributed, it overwhelmingly dominates at Gary, Indiana.

In the Ohio River, except East Liverpool, Ohio, two species of *Melosira* are abundant: *M. ambigua* and *M. granulata*. A large centric diatom *Stephanodiscus niagarae* variety *magnifica* is characteristic of the Klamath River. The Colorado, Snake and Yellowstone rivers often have fossil species of diatoms

The stations with the highest counts (productivity) are Peoria, Illinois; Ponca City, Oklahoma; St Paul, Minnesota; Keno, Oregon and Grand Forks, North Dakota.

While Gary, Indiana has the highest productivity of the Great Lakes stations, its counts are low when compared with those of high productive river stations. In general the lowest production stations are on the Great Lakes and in the Southeast.

Most of the 65 stations represented in this report have their highest counts during February–May. Only 13 of the 65 had their highest counts during October–January.

High temperatures and impounded water promote dense populations of blue-green algae in the late summer and early fall at several stations such as Cincinnati on the Ohio River.

Heavy turbidity drastically reduces the planktonic biota, particularly evident in the lower Missouri river.

Achnanthes minutissima, reported by ecologists to be an indicator of high dissolved oxygen, is common in the headwaters of the Columbia River.

Asterionella formosa and *Diatoma elongatum* become abundant during cold water seasons.

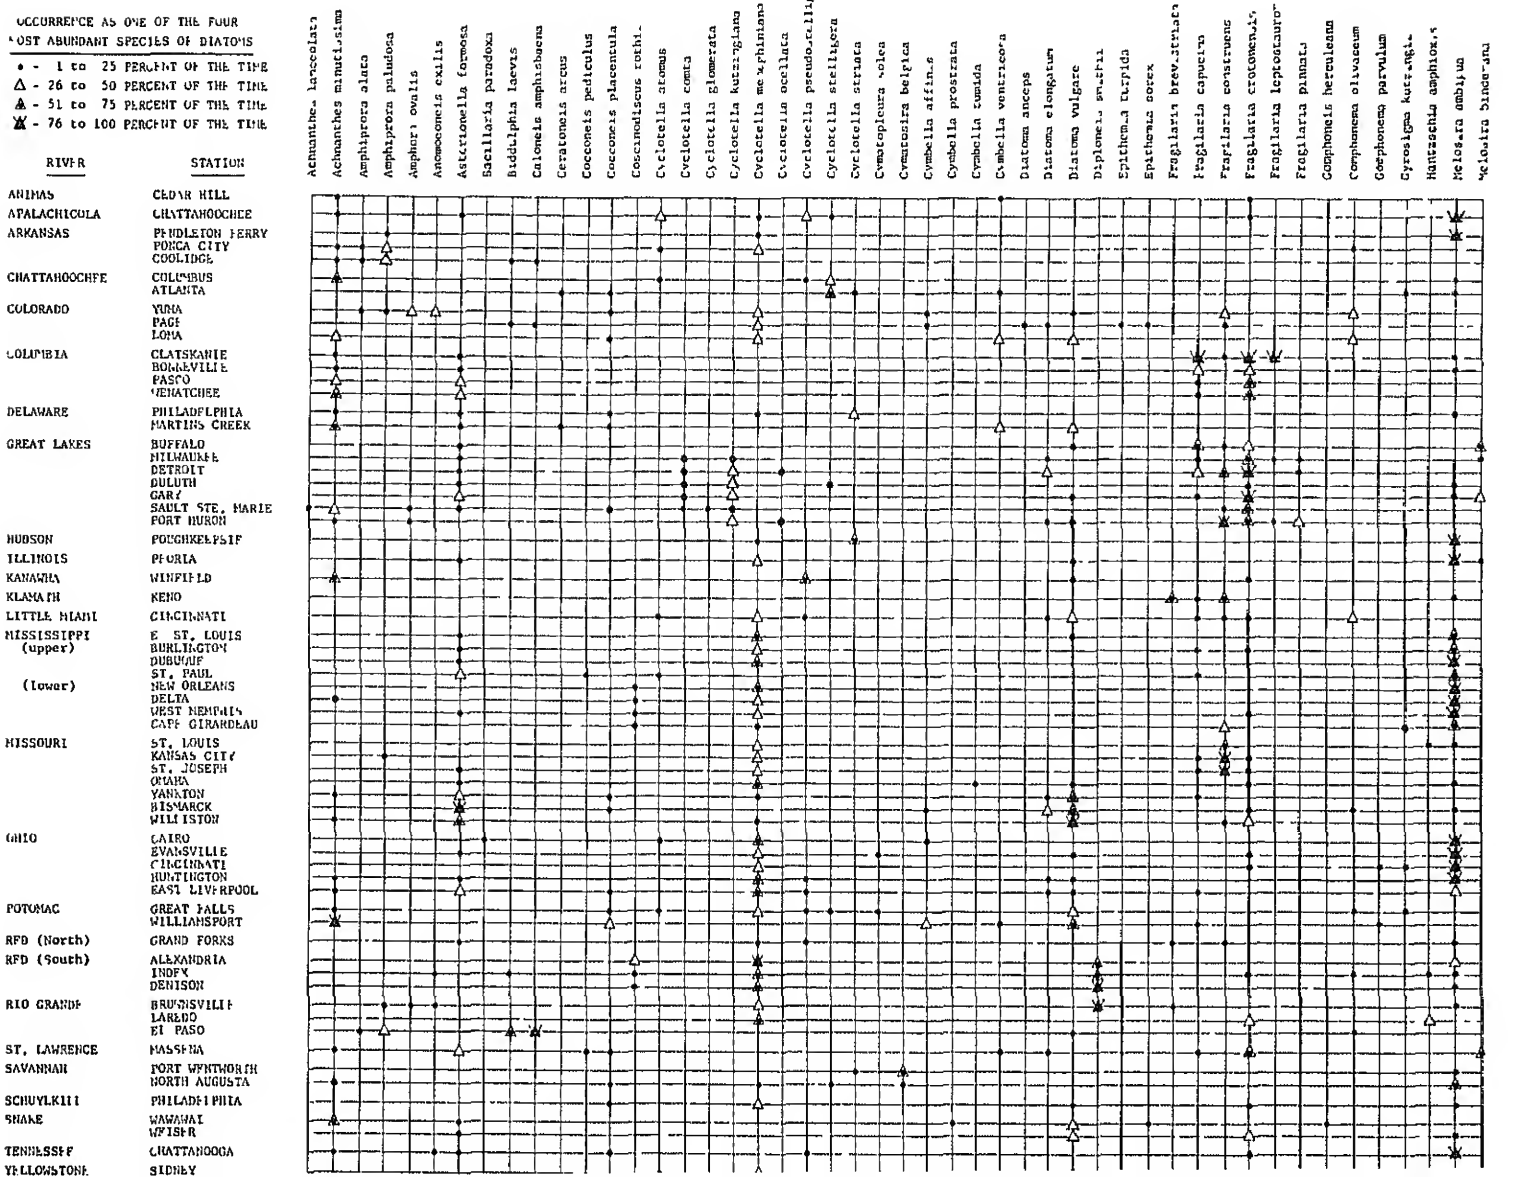
*Diatom Species Occurring at the Study Stations**

October 1959–June 1961

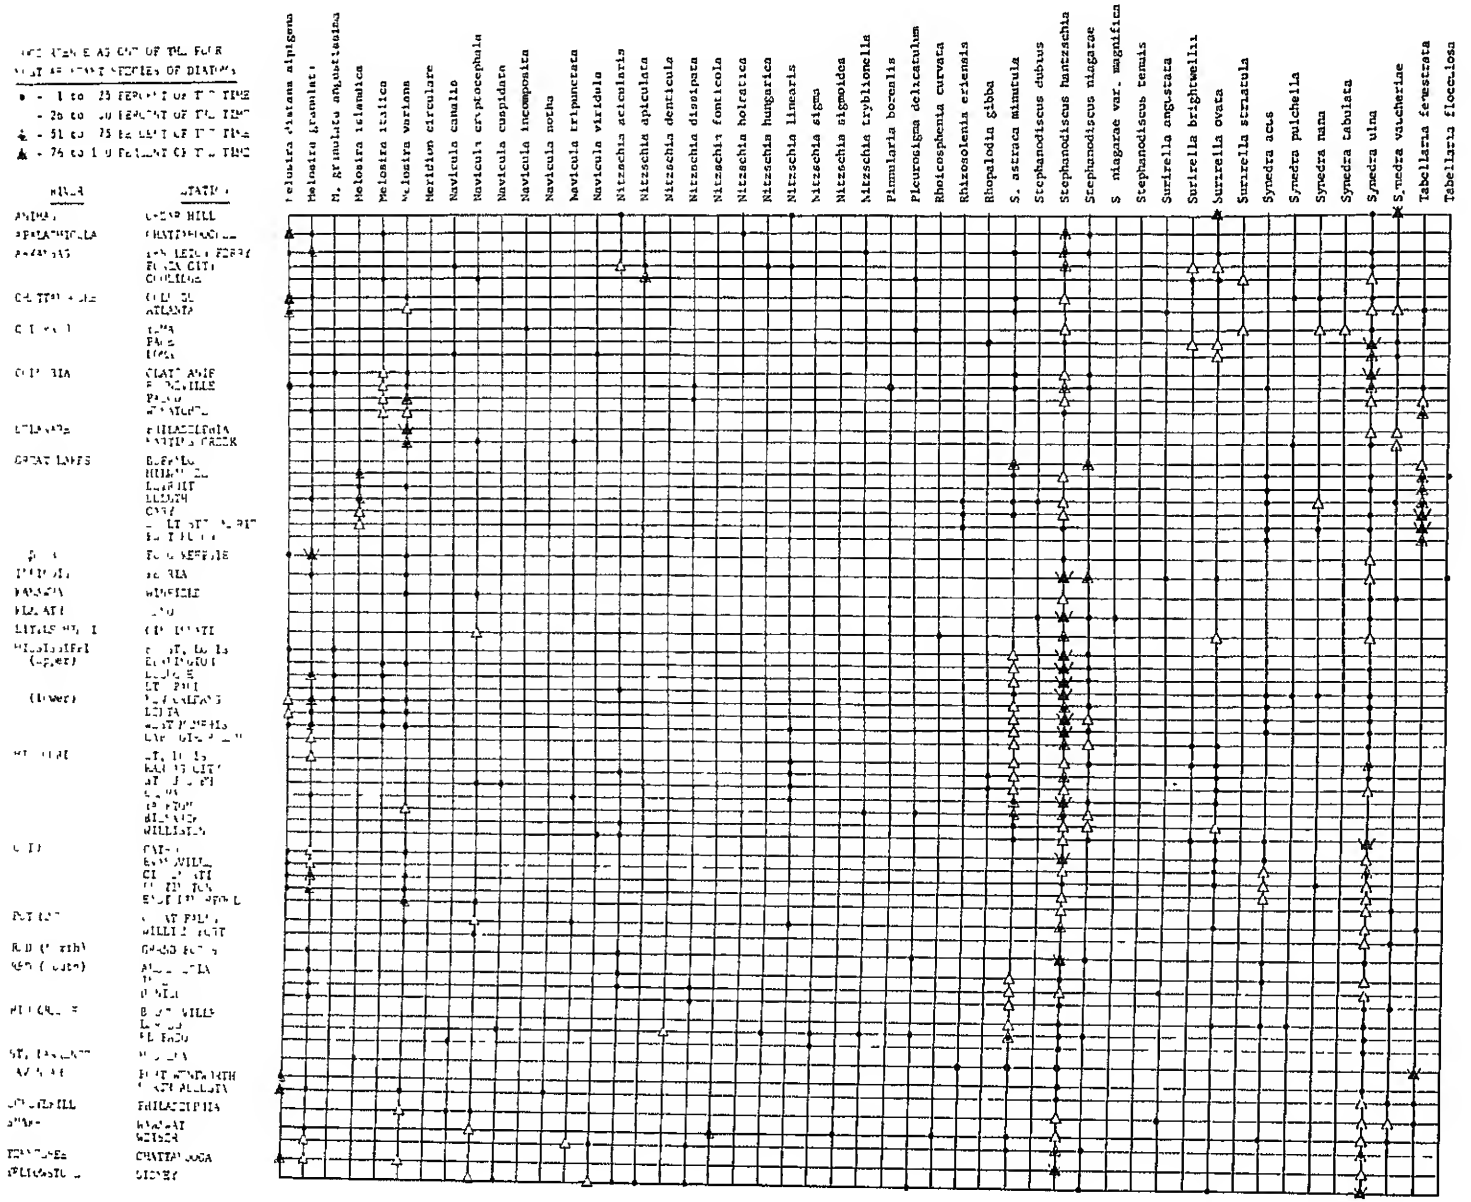
Achnanthes lanceolata Bréb.
Achnanthes minutissima Kütz.
Amphiprora alata Kutz.
Amphiprora paludosa W. Smith
Amphora ovalis Kutz.
Anomoeoneis exilis (Kutz) Cleve
Asterionella formosa Hassall
Bacillaria paradoxa Gmelin
Bidduiphia laevis Ehr
Caloneis amphisbaena (Bory) Cleve
Ceratoneis arcus Kutz
Cocconeis pediculus Ehr.
Cocconeis placentula Ehr.
Coscinodiscus rothii (Ehr.) Grun.
Cyclotella atomus Hust
Cyclotella comta (Ehr) Kütz.
Cyclotella glomerata Bachm.
Cyclotella kutzingiana Thwaites
Cyclotella meneghiniana Kutz
Cyclotella pseudostelligera Hust.
Cyclotella stelligera Cl. & Grun.
Cyclotella striata (Kg) Grun.
Cymatopleura solea (Bréb) W. Smith
Cymatosira beligica Grunow
Cymbella affinis Kutz
Cymbella tumida (Breb) Heurck
Cymbella ventricosa Kutz.
Diatoma anceps (Ehr.) Grunow
Diatoma elongatum C A. Agardh
Diatoma vulgare Bory
Diploneis smithii (Bréb.) Cleve
Epithemia turgida (Ehr) Kutz.
Epithemia zorex Kutz.
Eunotia pectinalis (Kutz) Raben.
Fragilaria brevistriata Grun.
Fragilaria capucina Desm.
Fragilaria construens (E.) Grun.
Fragilaria crotonensis Kitton
Fragilaria leptostauron (Ehr.) Hust.
Fragilaria pinnata Ehr.
Fragilaria virescens Ralfs.
Frustulia vulgaris Thwaites
Gomphoneis herculeana (Ehr.) Cleve
Gomphonema olivaceum (Lyngb.) C. Ag.
Gomphonema parvulum Kütz.
Gyrosigma kutzingii (Grun.) Cleve
Hantzchia amphioxys (Ehr.) Grun.
Melosira ambigua (Grun.) O. Müller
Melosira binderana Kg.
Melosira distans (Ehr.) Kütz.
var. alpigena Grun.
Melosira granulata (Ehr.) Ralfs.
Melosira islandica O. Müller
Melosira varians C. A. Agardh
Meridion circulare (Grev.) C. A. Ag.
Navicula canalis Patrick
Navicula contenta Grun.
Navicula cryptocephala Kütz.
Navicula cuspidata Kutz.
Navicula hungarica Grun.
Navicula mutica Kütz.
Navicula notha Wallace
Navicula tripunctata (Mull.) Bory
Navicula viridula Kütz.
Nitzschia acicularis (Kütz.) W. Smith
Nitzschia apiculata (Gregory) Grun.
Nitzschia denticula Grun.
Nitzschia dissipata (Kütz.) Grun.
Nitzschia filliformis (W. Smith) Hust.
Nitzschia fonticola Grun.
Nitzschia holsatica Hust.
Nitzschia hungarica Grun.
Nitzschia linearis W. Smith
Nitzschia parvula Levis
Nitzschia sigma (Kütz.) W. Smith
Nitzschia sigmoidea (Ehr.) W. Smith
Nitzschia tryblionella Hantzsch
Pinnularia borealis Ehr.
Pleurosigma delicatulum W. Smith
Rhoicosphenia curvata (Kütz.) Grun.
Rhizosolenia eriensis H. L. Smith
Rhopalodia gibba (Ehr.) O. Müller
Stephanodiscus astraea (Ehr.) Grun.
var. minutula (Kütz.) Grun.
Stephanodiscus dubius (Fricke) Hust.
Stephanodiscus hantzschii Grun.
Stephanodiscus niagarae Ehr.
Stephanodiscus niagarae Ehr.
var. magnifica Fricke
Stephanodiscus tenuis Hust.
Surirella angustata Kütz.
Surirella brightwellii W. Smith
Surirella ovata Kütz.
Surirella striatula Turpin
Synedra acus Kütz.
Synedra pulchella Kütz.
Synedra nana Meister
Synedra tabulata (C. Ag.) Kütz.
Synedra ulna (Nitzsch) Ehr.
Synedra vaucheriae Kütz.
Tabellaria fenestrata (Lyngb.) Kütz.
Tabellaria flocculosa (Roth) Kütz.

*Each species listed occurred one or more times in aggregate samplings as one of the four most abundant recorded at study stations in the 15 waterways involved.

Occurrence of Four Most Abundant Diatom Species



Occurrence of Four Most Abundant Diatom Species (continued)



Green Flagellates at 48 Stations

Because of the interest of some researchers in the use of green flagellate algae as potential indicators of organic enrichment, the compilation below is presented.

Semimonthly samples were used, beginning with the second sample in July 1960 through September 1961. Only those stations having uninterrupted sampling for this period are included. Average green flagellate counts for 48 stations for the 15-month period are shown below.

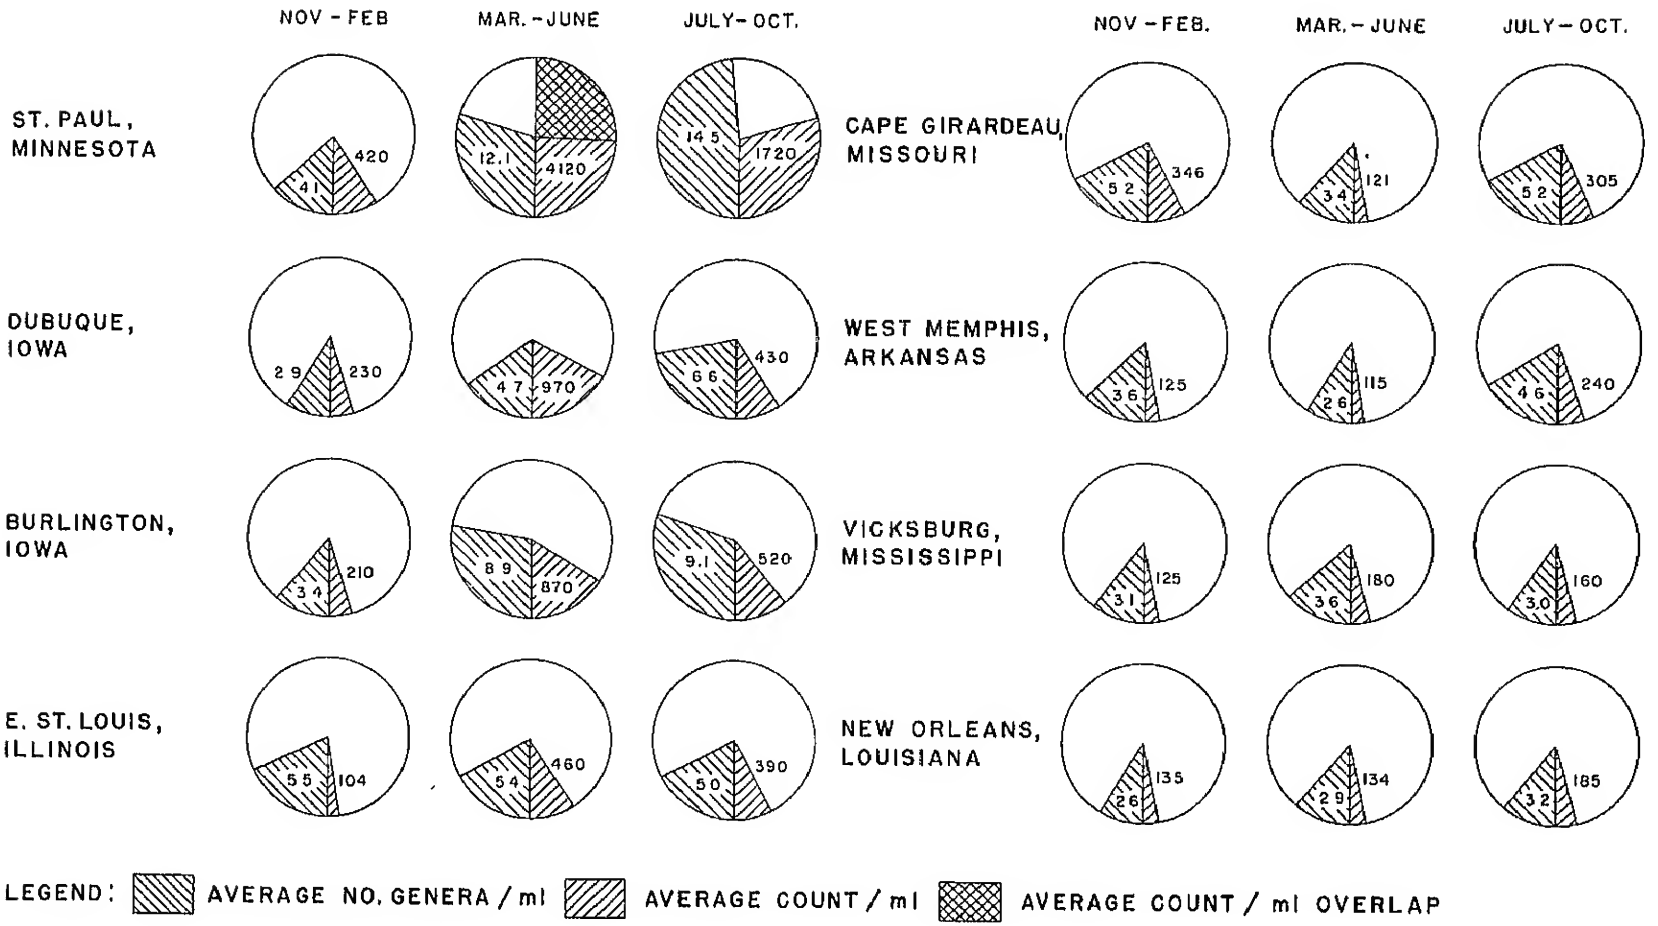
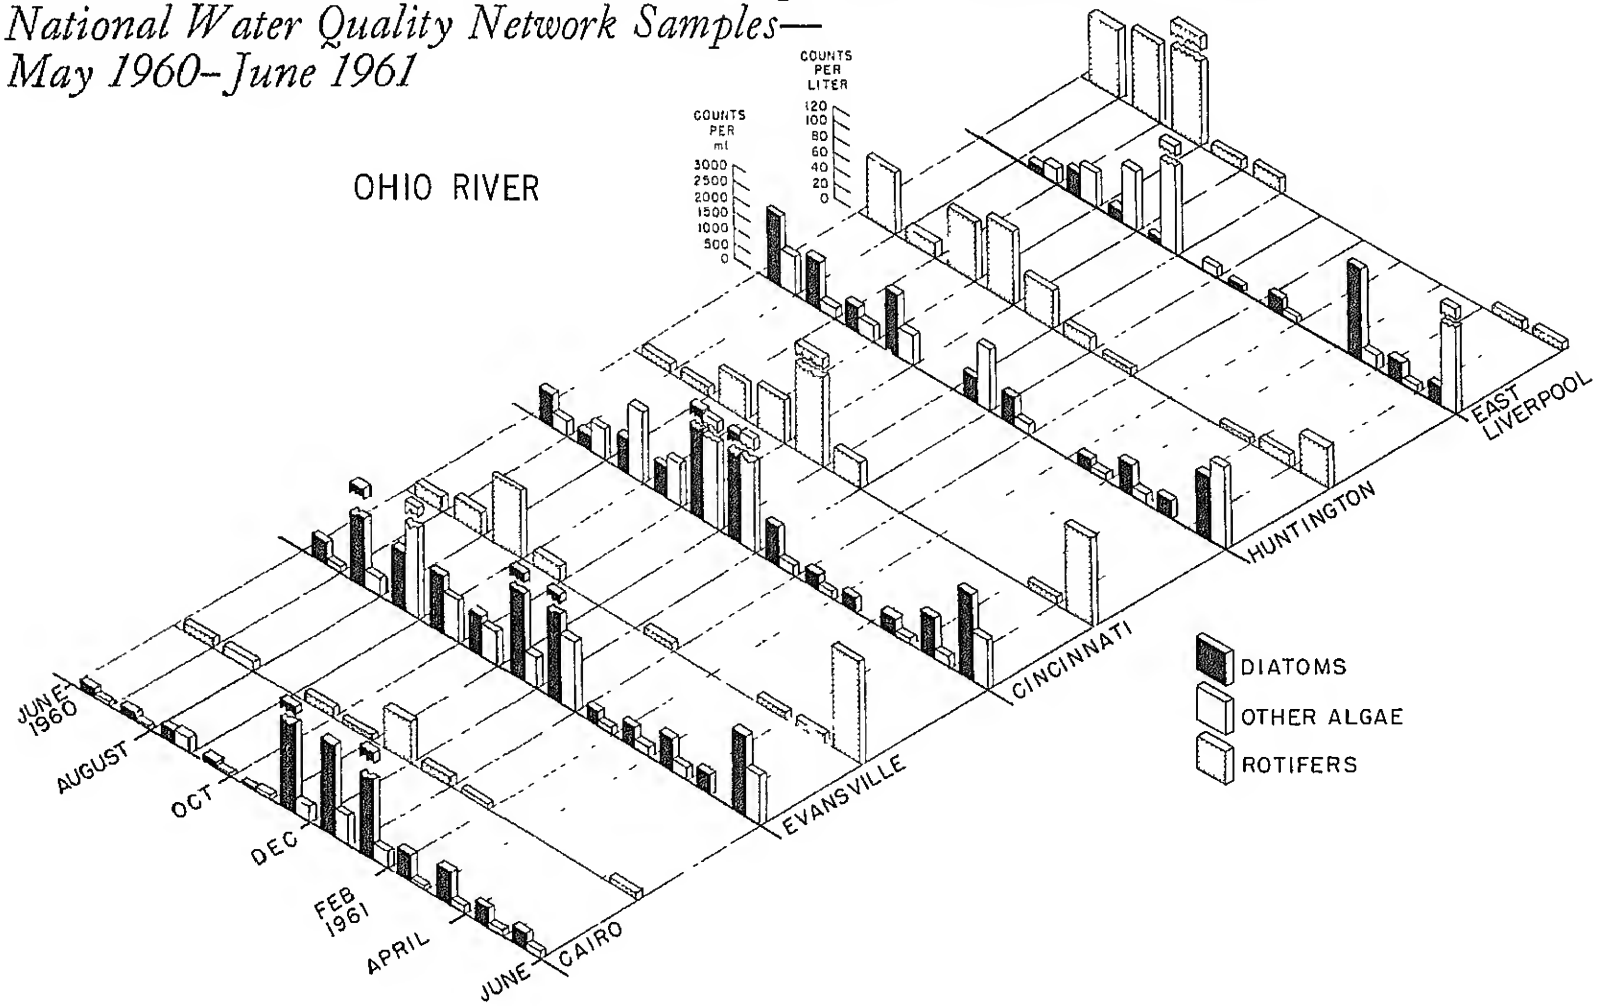
Planktonic Green Algae, Mississippi River—1959



Similarities or differences between sampling stations can be observed through separate reporting of the three major groups, diatoms, green flagellates, and rotifers. Charted above are planktonic green algae (nonflagellates) 4-month averages for the year 1959 at eight Mississippi River stations. The count decreases successively station by station dowstream from St. Paul, Minn. to New Orleans, La. The average count per ml. for the whole year was 2,087 at St. Paul and 151 at New Orleans.

Relative Abundance of Diatoms, Other Algae and Rotifers, Ohio River National Water Quality Network Samples— May 1960–June 1961



Production by planktonic algae and consumption by planktonic rotifers has an important bearing on water quality. Wastes discharged into rivers may produce problems from overproduction by diatoms and other algae and underconsumption by microinvertebrates as the natural self-purification process takes place. To maintain water of high quality a balance of production and consumption is a desirable objective of stream management. A graphical presentation of this relationship for 5 sampling stations on the Ohio River is shown. Along the Ohio River the highest standing crops were observed during the late summer and early fall when flow rates are the lowest. Cincinnati, the midpoint station between the headwaters and river mouth, had the highest productivity of the 5 sampling stations.

*Semimonthly samples from 65 Stations of the National Water Quality Network.

Explanation Of Sampling Station Charts

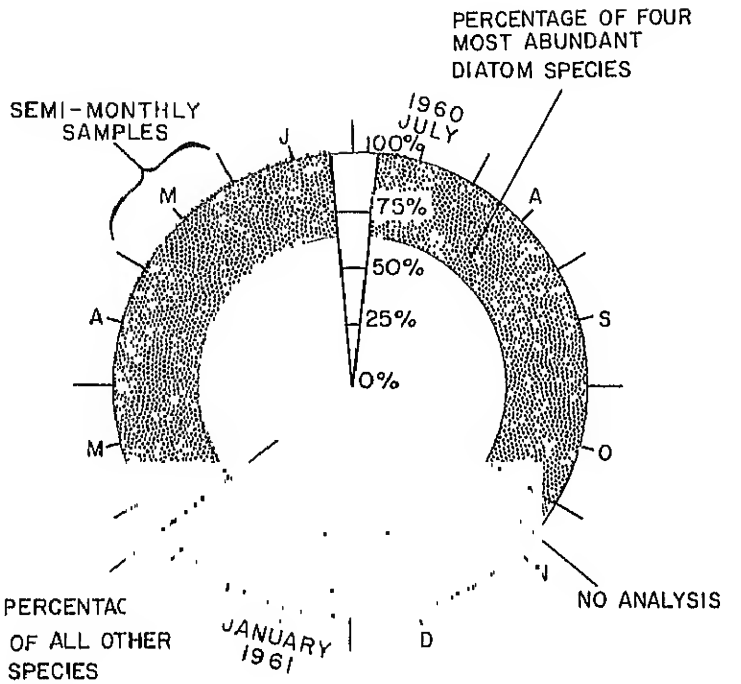
A. BAR GRAPH—Percent Occurrence and Relative Abundance of Diatoms.

The quality of surface waters at a given time may be indicated by the kinds and numbers of organisms they support. One effect of enrichment is a decrease in the diversity of the diatom species. The identification and relative abundance of the predominant diatom species is basic to the determination of their species diversity.

The bar graph, "Diatoms—Present Occurrence," lists those species of diatoms which appeared first, second, third or fourth in abundance in semimonthly samples taken during the period designated at 65 stations of the National Water Quality Network for the year beginning July 1, 1960. For those species in first or second place at any time, the graph presents the percent of the time they occurred as either first, second, third or fourth in abundance. For instance, in the Columbia River at Clatskanie, Oregon, *Synedra ulna* was the number one species 19 percent of the time, was in first or second place 32 percent of the time, was among the first three predominant species 51 percent of the time, and was among the first four 76 percent of the time. Species which never occurred in first or second place, but which did occur in third or fourth are listed, but their percent occurrence is not shown.

The percent occurrence in no way reflects the actual population density. A species second in abundance, for example, may be present in only small numbers; another may have occurred in large numbers in some samples, but because it was not among the first four, would not be listed.

Both the bar and circle graphs (see B, p. 25) deal with the same



DIATOMS COUNTS / ml.	CIRCLE SIZE
0-1000	SMALL
1001-3000	MEDIUM
3001-OR OVER	LARGE

sampling period. The bar graph includes species names and comprises one year's collection of data.

B. CIRCLE GRAPH—Diatoms, Species Diversity (See diagram at left).

While the bar graph is designed to show the percent occurrence and names of the four most abundant species for a year, the circle graph indicates the species diversity of diatoms at each of the 24 (semimonthly) sampling times for the year July 1960 through June 1961. Semimonthly samples are represented by radial lines extending from the perimeter of the circle. The short radial lines with month designations represent the second semimonthly samples normally taken during the third week of the month. The longer lines represent the first of the semimonthly samples. The months are recorded consecutively clockwise.

A total diatom population range is expressed in the size of the circle. Three circle sizes are used. A small circle (4 cm. in diameter) represents a diatom count of between zero and 1,000 per ml., a medium circle (6 cm. in diameter), between 1,001 and 3,000 per ml., and a large circle (8 cm.) above 3,001.

A total diatom population of any sample is represented as a percent by the radius designated for that sample. The percent of diatoms, other than the four most abundant species in a population, is determined by the distance from the center of the circle to a point on the radius. A quartile scale is given on a vertical radius of each circle. The central blank portion of the circle is formed by radially plotting percent of diatoms other than the four most abundant species Sections shaded by the smaller dots represent samples not analyzed. Species diversity is indicated by the extension of the white area from the center of circle. Thus a line drawn to connect these points on the 24 radii inscribes a figure or pattern which may be characteristic for each station. As the central clear area extends outward greater species diversity is indicated. Correspondingly, less diversity is indicated as the outer dark area increases.

The perimeter is divided into evenly spaced sampling times and each circle graph shows the fluctuations in species diversity between the 24 sampling times during the year. For example, species diversity is relatively great at Wawawai, Washington on the Snake River and relatively low at Grand Forks, North Dakota on the Red River. Many of the 65 circle graphs suggest seasonal patterns, with the least species diversity in late summer and fall. At Clatskanie, Oregon on the Columbia River, species diversity is greater during the winter months than the summer months.

C. LOGARITHMIC LINE GRAPH—Total Live Phytoplankton Counts.

Total live phytoplankton counts are plotted beginning with July 1959 for those stations that were in operation at that time. Counts are presented in a logarithmic scale on the vertical axis. The counts exclude the inert diatom shells. A summary of average seasonal total live phytoplankton counts is also presented. Seasonal periods averaged extend from June–September, October–January, and February–May.

D. TABLE OF ZOOPLANKTON

Four genera of rotifers were found to be very common in the major waterways of the United States by this study. The occurrence of these genera during the period July 1960 to July 1961 is presented with average counts per liter per sample. Column one presents the number of occurrences of all rotifers present in all samples. The second column gives the average count per liter based on all samples, whether or not rotifers were present.

Similar treatment is given copepods, cladocerans, nauplii, nematodes and other invertebrate metazoans.

E. TABLE OF MOST ABUNDANT GENERA OF ALGAE

The most abundant genera of algae are recorded in tabular form, the criterion for inclusion being occurrence in numbers 150 per ml. or more. The percent occurrence in these numbers is presented. The table is broken down into major groups (blue-greens, greens, green flagellates, other pigmented flagellates, diatoms—centric and pennate). This permits comparisons among these major groups of algae.

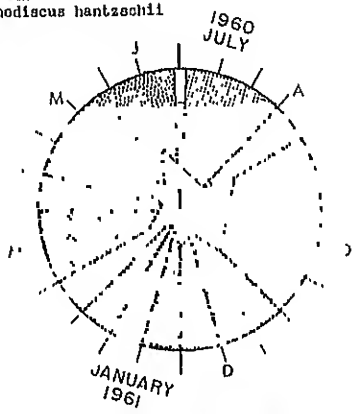
Samples analyzed 16
July 1960 to July 1961

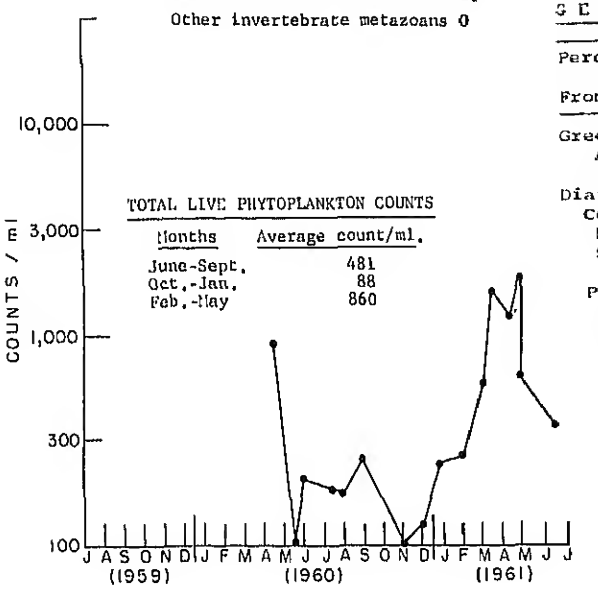
	Samples with Animals	Average count per liter per sample
Rotifers.	16	16.0
Keratella	15	7.3
Polyarthra	5	0.8
Brachionus	6	1.1
Synchaeta	6	0.6
Other genera	15	10.8
Crustaceans:		
nauplii	3	0.7
copepods	4	0.3
cladocerans	3	0.3
Nematodes		1.
Other invertebrate metazoans		0

MOST ABUNDANT GENERA OF ALGAE

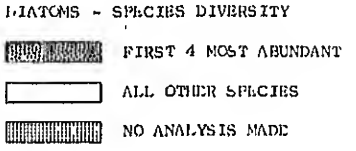
Percent frequency of counts 150 per ml. or more
From April 1960 to August 1961

Green algae	
Ankistrodesmus	10
Diatoms	
Centric	
Melosira	21
Stephanodiscus	31
Pennate	
Asterionella	10
Fragilaria	5
Tabellaria	15

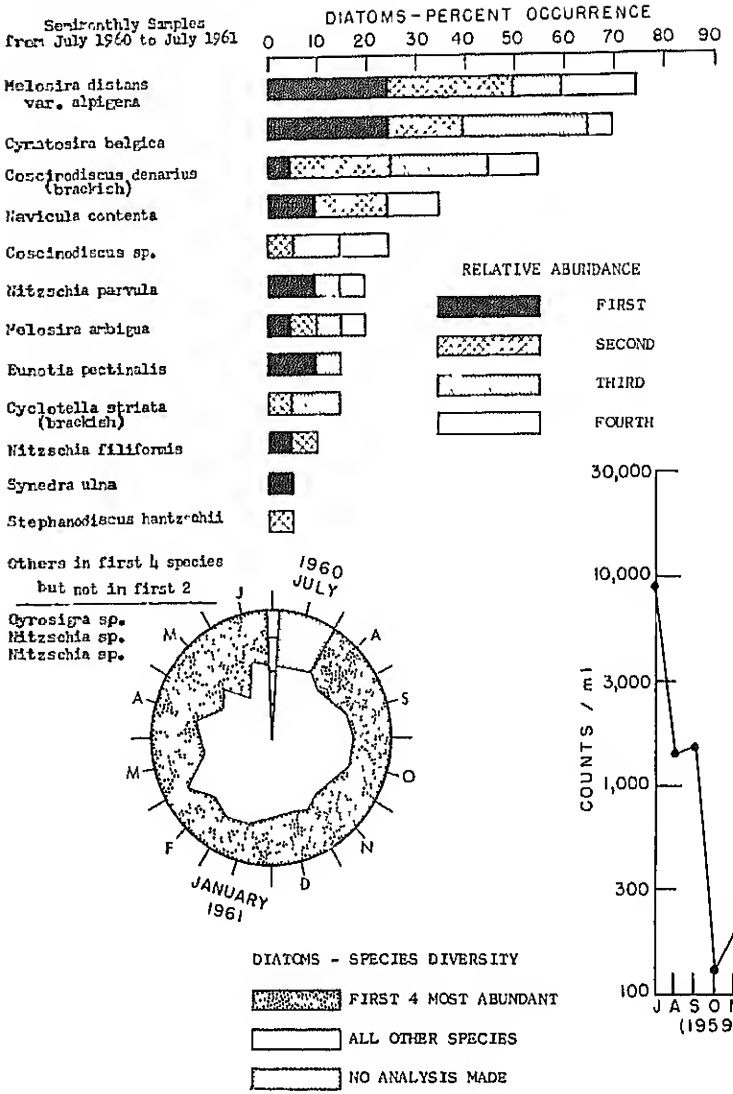




Months	Average count/ml.
June-Sept.	481
Oct.-Jan.	88
Feb.-May	860



SAVANNAH RIVER
PORT WENTWORTH, GEORGIA



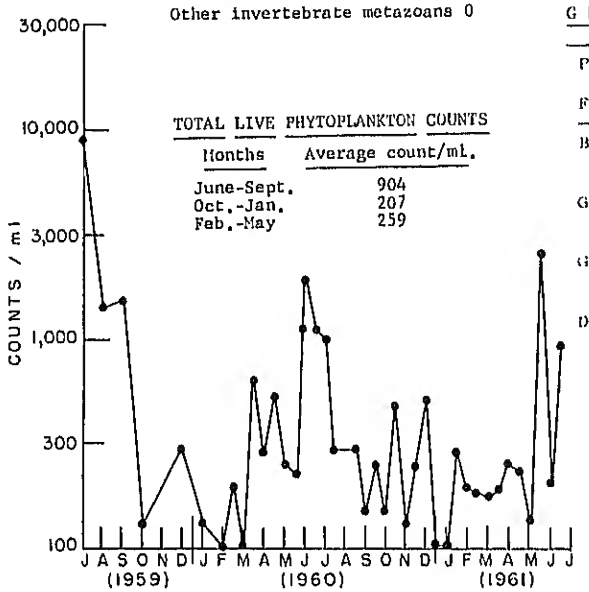
ZOOPLANKTON

Samples analyzed 22
July 1960 to July 1961

	Samples with Animals	Average count per liter per sample
Rotifers	9	1.0
Keratella	3	0
Polyarthra	4	0
Brachionus	1	0
Synchaeta	0	0
Other genera	3	0
Crustaceans:		
nauplii	0	0
copepods	4	0.2
cladocerans	1	0.1
Nematodes		1.0
Other invertebrate metazoans		0

TOTAL LIVE PHYTOPLANKTON COUNTS

Months	Average count/ml.
June-Sept.	904
Oct.-Jan.	207
Feb.-May	259



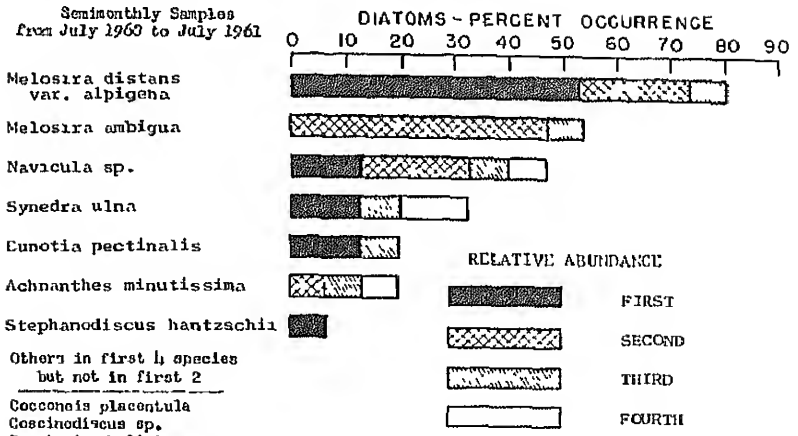
MOST ABUNDANT GENERA OF ALGAE

Percent frequency of counts
150 per ml. or more
From May 1959 to May 1961

Blue-green algae	
Anacystis	2
Green algae	
Ankistrodesmus	2
Green flagellates	
Chlamydomonas	*
Diatoms	
Centric	
Cyclotella	7
Melosira	17
Stephanodiscus	2
Pennate	
Synedra	9

SAVANNAH RIVER
NORTH AUGUSTA, SOUTH CAROLINA

Semimonthly Samples
from July 1960 to July 1961



Others in first 4 species but not in first 2

Cocconeis placentula
Coscinodiscus sp.
Cymatosira beligica
Cyclotella meneghiniana
Cyclotella stelligera
Melosira granulata
Melosira varians
Melosira sp.
Navicula notha
Navicula sp.
Synedra vaucheriae
Tabellaria fenestrata

ZOOPLANKTON

Samples analyzed 15
July 1960 to July 1961

	Samples with Animals	Average count per liter per sample
Rotifers.	6	2.0
Keratella	4	1.0
Polyarthra	4	1.0
Brachionus	0	0
Synchaeta	0	0
Crustaceans:		
nauplii	3	0.4
copepods	2	0.2
cladocerans	0	0
Nematodes		0
Other invertebrate metazoans		0
